1 | CURRICULUM VITAE

Prior to my time at BCIT, my computer programming skills were entirely self-taught. As such, it has been my objective at BCIT to formalize and hone my skills with respect to computer programming as well as expanding my knowledge into other sub-disciplines, such as data communications and network security.

Ultimately, upon graduation, my goal is to seek employment in the field of *NIX/BSD systems programming with a focus on data communications. With this goal in mind, I have constructed an experimental practicum with a focus on the skills that I have learnt during my tenure at BCIT.

1.1 FORMAL EDUCATION

My formal education has been somewhat fragmented as I have had several false starts over the past 20 years. Due to personal issues, I ended up dropping out of high school in 1994, which I ultimately finished at night school in 2002.

After a brief stint at UBC with an eye on physics, I decided to enrol at BCIT with the intention of completing the Bachelor of Technology program.

- 2007 - 2012 British Columbia Institute of Technology**
Bachelor of Technology Program - Dual Option:
- *Network Security & Administration*
- *Data Communications & Internetworking*
- 2003-2004 University of British Columbia**
Bachelor of Science 1st Year - Physics
- 2001-2002 Main Street Education Centre**
Completed Grade 12
- 2001-2002 Lucas Centre**
Completed Grades 10 & 11
- 1992-1994 Semiahmoo Secondary School**
Completed Grades 8 & 9

1.2 WORK EXPERIENCE

The majority of my work experience has been with Highlight Investments, as I helped found the company and remained with there for 13 years. During my time with Highlight Investments I was afforded the opportunity to learn how to program perform systems and network administration. This included the administration of our co-located web, firewall, email, and database servers.

With the launch of our main stock index volume analysis tools, new development ceased and the company moved into maintenance mode. Given the lack of new and interesting projects to work on, I decided to go back to school in order to further my career.

1997-2010 Highlight Investments Research Group

Systems Support & Operations - Stock Index Volume Analysis

- Pivotal role in creating & incorporating the company
- Designed prototype stock market analysis tools
- Patented a stock volume normalization technique
- Published in *The Technical Analyst* magazine
- Linux & Windows systems & network administration
- Retained for consulting

1996-1997 Kona Norgren Enterprises

Owner/Operator - Floral Delivery

- Accounting, taxes, & payroll
- Delivery & courier dispatch
- Day-to-day management & administration

1992-1996 Nectar Concepts Inc.

Computer Consultant - Snowboard Manufacturer

- Created CAD/CAM drafting solution for manufacturing
- Created & maintained office coaxial network
- Systems administration & maintenance

1.3 AREAS OF SPECIALIZATION

The majority of my work over the past decade has focused on some area of network security and data communications (e.g. the delivery of real-time stock market data and securing database servers from SQL injection attacks). What I gained throughout my career is a better understanding of what I find truly fascinating with respect to my field: low-level systems programming.

I am currently nearing the end of my Bachelor of Technology degree at BCIT; with a dual option in Network Security and Data Communications. It is with these specializations and my interest in low-level systems programming in mind that I have designed a practicum that draws from each area of expertise in order to more fully make use of what I have learnt during my time with the program.

2 | PROJECT INFORMATION

This practicum is primarily an exploration into FreeBSD kernel modules with respect to covert data communications. The main functionality of this system will be to allow any single node within the network to exfiltrate data from any other node within the network. However, with respect to being a covert network, the kernel module will be responsible for misreporting the state of network connections to the operating system. This will make any cursory inspection of active network connections mislead the operator into thinking everything is operating normally.

In addition to data exfiltration from any particular node in the network, one will also be able to make use of the network as a proxy for standard HTTP requests; much like a Tor¹ network.

Throughout my exploration of this practicum, I will attempt to implement the following major features:

- Network topology modelled after mesh networks².
- Kernel-based encryption for all network communication.
- Ability to use the network in a Tor-like fashion for standard HTTP requests.
- Exfiltration of data from any node within the network.
- Near real-time interaction with any node via standard command-line interface.
- Implementation of client/server functionality as loadable FreeBSD kernel modules.
- Kernel modules mask their existence from any users on the system.

¹ <https://www.torproject.org>

² http://en.wikipedia.org/wiki/Mesh_networking

- Kernel modules hook into system network calls in order to hide traffic from internal inspection within the system.

2.1 BACKGROUND INFORMATION

For a network to be as robust as possible, topology matters. In this case, I have chosen a standard mesh topology where each node can connect to any other node within the network. However, this doesn't necessarily mean that each node is constantly connected to every other node in the network at once. In fact, it will be how packets are routed from node to node that will adopt a mesh-like topology.

Figure 1: Possible connections within a mesh network.

From the above graph, once and see that the network consists of nodes where each node is connected to every other node in the network. This is a basic mesh network topology. Such a network is very resilient to any type of disruption, for the removal

of any nodes will not disrupt the network as a whole. From a security standpoint, if any particular node were compromised (by the good guys in this case), one could ascertain the identity of all member nodes within the network. However, this does not necessarily mean that the identity of the individual who compromised the network is specifically at risk – more on this later.

Routing within the network will depend on which node the infiltrator is connected to. For example, if the infiltrator is communicating with node #1, but wants to exfiltrate data from node #8 or make a Tor-like HTTP request, the system will route the request along a random path using a random number of hops³. Communication with node #1 (in order to reduce the chances of discovery) will be accomplished with specially formatted ICMP messages with a forged source address.

Figure 2: Example of random routing from node #1 to node #8.

³ The hops may take the form of $\text{rand}(1 \dots n - 1)$ nodes.

In order to reduce the chances of the infiltrator's identity being discovered, we need to implement a way for the client/server application to be hidden from casual inspection of the system itself. This can be achieved though implementing the client/server software as a loadable kernel module. As explained in *Fun and Games with FreeBSD Kernel Modules*⁴, with a kernel module we can both hide the process itself (along with the kernel module we loaded and any subsequent children created) and even the desired network activity from the rest of the system completely. What this would mean is that if the user were to preform a 'ps -aux' or a 'netstat -nav' command, neither's results would betray the existence of the kernel module itself. Additionally, network traffic itself may possibly be hidden from the view of a raw packet dump using 'tcpdump'⁵.

⁴ <http://www.r4k.net/mod/fbsd.fun.html>

⁵ This may possibly need to be compiled into the kernel, as this falls outside the domain of simply hooking into system calls.

2.2 METHODOLOGY

The exploration of this practicum can be divided up into several discrete modules, which can then be integrated. The following sections will briefly outline each module and its function.

2.2.1 Network Building

Given a list of node from which to build a network, the initial node will communicate the entire list of addresses with a random node in the network. As stated earlier, all communications between nodes will be encrypted. This node will then communicate the entire list of addresses with another random node. The difference here is that as we progress through the mesh, nodes to which the list has already been communicated will be marked in order to avoid randomly connecting with a node that has already received the list of addresses.

What this means is that the number of possible random connections will decrease until there is only one possible node to which the list of addresses can be communicated.

In the event that a node is removed from the network or becomes inaccessible, that node will be removed from each node's list of possible connections. However, if the offending node becomes active once again, it will be reincorporated into the network as soon as it initiated communication with any of the active nodes.

2.2.2 FreeBSD Kernel Modules

One of the main features of this project is the creation of a loadable kernel module for FreeBSD that is able to mask its presence from the process table and selectively hide network traffic from utilities such as tcpdump. In order to achieve this, the kernel module needs to intercept the various ways information about processes is obtained. Also it will have to keep track of which processes need to be hidden. Every process is recorded in a struct proc. By extension, hiding network connections also requires intercepting system calls.

2.2.3 Data Transfer

With the kernel module hiding the associated network traffic from the user, we may be able to forgo data obfuscation within TCP/IP headers, thereby allowing for higher throughput while still remaining unnoticed to the user. As such, large transfers of data may be able to go unhindered. However, if this is not the case (after further experimental research into FreeBSD kernel modules), implementation of an obfuscation scheme may become necessary.

2.2.4 Encryption

With normal user-land software, network communication can be easily encrypted using OpenSSL libraries. However, because kernel modules do not have access to anything that is not provided within the kernel itself, I will need to make use of any built-in encryption that the kernel provides. Failing this, I will need to implement my own encryption routines from scratch.

Given this limitation, key exchange between nodes could be simplified by using a single encryption key across the entire network. It may be possible to devise a scheme where each node's connection with another uses a different key, but this entirely hinges on the type of encryption the kernel provides, if any.

2.2.5 Testing & Implementation Environment

Ideally, only a single virtualized copy of FreeBSD using FreeBSD will be needed. In order to simulate a multitude of individual systems with a single virtualized copy of FreeBSD, a feature of FreeBSD called 'jails' may be employed. With FreeBSD jails it is possible to create various different virtual machines, each of them having their own set of utilities installed and their own configuration. This makes it a safe way to try out software. For example it is possible to run different versions or try different configurations of Apache in different jails. And since the jail is limited to a narrow scope, the effects of a misconfiguration or

mistake (even if done by the in-jail superuser) does not jeopardize the rest of the system's integrity.

However, the use of loadable kernel modules from within a jail may be suspect. If it is not possible to use FreeBSD jails along with kernel modules, a virtualization environment using VMWare where each node has its own virtualized copy of FreeBSD could be implemented. This would allow for the concurrent running of multiple iterations of FreeBSD in order to test a network of nodes. The memory requirements of a base FreeBSD system are minimal, therefore with 21 (for example) virtualized environments, each with 256MB of RAM, only a total of 5376MB of RAM will be required. The current testing system has 8192MB of RAM and makes use of a high-end Intel Core i7 processor. If this proves to be too much for the system, virtualization may be spread among several computer systems.

2.2.6 Prototyping

Given the exploratory nature of this practicum, I will be going with an incremental software prototyping approach to development. Small-scale mock-ups of each part of the system, outlined above, will be developed following an iterative modification process until the prototype evolves to meet the system's requirements.

For instance, the first task will be that of creating a loadable FreeBSD kernel module that is able to mask specific network connections. This will then expand into having the kernel module intercept and manage communications between multiple nodes. However, because of the exploratory nature of this practicum, a rigid development and integration plan is not feasible. This is why I will be focusing on creating iterative prototypes, slowly adding features to each iteration until a base level of functionality has been achieved.

2.3 TECHNOLOGIES USED

There is a prolific amount of information on the Internet with respect to using kernel modules in order to 'root' or exploit Linux or Windows systems. However, such information with respect to FreeBSD systems is either exceptionally out of date (and therefore no longer applicable or relevant) or simply non-existent. Because of this limiting factor, my explorations into accomplishing the goals of this project will have little or no precedent.

Programming Language: C/C++

Operating System: FreeBSD 9.0

Network Topology: Mesh Network

Security Implementation: Process and network connection hiding using FreeBSD loadable kernel modules. Direct interception of system calls in order to sanitize undesirable connection information from any user on the system.

Virtualization Environment(s): FreeBSD running as a guest on VMWare workstation 8.0. Additionally, the virtualized FreeBSD environment may make use of jails in order to virtualize and simulate any size of network. For example, I may initiate 32 jail environments in order to simulate a mesh network of 32 nodes. Each virtualized environment will be able to collect data particular to that environment, such as raw TCP/IP dumps and process information.

2.4 TESTING PLAN

2.4.1 Unit Testing

2.4.2 Functional Testing

2.5 SCHEDULE & MILESTONES

2.5.1 Research

2.5.2 Environment Setup

2.5.3 Proof of Concept Prototypes

2.5.4 Programming

2.5.5 Testing & Debugging

2.5.6 Documentation & Final Report
